# Multinomial Discrete Choice: Nested Logit and GEV

Chris Conlon

Grad IO

Fall 2025

## Multinomial Logit: IIA

The multinomial logit is frequently criticized for producing unrealistic substitution patterns

- ▶ Suppose we got rid of a product k then  $s_{ij}(\mathcal{J} \setminus k) = s_{ij}(\mathcal{J}) \cdot \frac{1}{1-s_{ik}}$ .
- lacksquare Substitution is just proportional to your pre-existing shares  $s_j$
- No concept of "closeness" of competition!

### Can we do better?

#### Multinomial Probit?

- ▶ The probit has  $\varepsilon_i \sim N(0, \Sigma)$ .
- $\triangleright$  If  $\Sigma$  is unrestricted, then this can produce relatively flexible substitution patterns.
- Flexible is relative: still have normal tails, only pairwise correlations, etc.
- ▶ It might be that  $\rho_{12}$  is large if 1, 2 are similar products.
- ► Much more flexible than Logit

#### Downside

- $\triangleright$   $\Sigma$  has potentially  $J^2$  parameters (that is a lot)!
- ▶ Maybe J\*(J-1)/2 under symmetry. (still a lot).
- **Each** time we want to compute  $s_i(\theta)$  we have to simulate an integral of dimension J.
- ▶ I wouldn't do this for  $J \ge 5$ .

# Relaxing IIA

Let's make  $\varepsilon_{ij}$  more flexible than IID. Hopefully still have our integrals work out.

$$u_{ij} = V_{ij} + \varepsilon_{ij}$$

- $\triangleright$  One approach is to allow for a block structure on  $\varepsilon_{ij}$  (and consequently on the elasticities).
- ightharpoonup We assign products into groups g and add a group specific error term

$$u_{ij} = V_{ij} + \eta_{ig} + \varepsilon_{ij}$$

- ▶ The trick putting a distribution on  $\eta_{ig} + \varepsilon_{ij}$  so that the integrals still work out.
- Do not try this at home: it turns out the required distribution is a special case of GEV (more on this later) and the resulting model is known as the nested logit.

A traditional (and simple) relaxation of the IIA property is the Nested Logit. This model is often presented as two sequential decisions.

- First consumers choose a category (following an IIA logit).
- Within a category consumers make a second decision (following the IIA logit).
- ► This leads to a situation where while choices within the same nest follow the IIA property (do not depend on attributes of other alternatives) choices among different nests do not!

## Alternative Interpretation

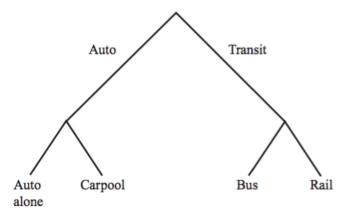

Figure 4.1. Tree diagram for mode choice.

Utility looks basically the same as before:

$$U_{ij} = V_{ij} + \underbrace{\eta_{ig} + \widetilde{\varepsilon}_{ij}}_{\varepsilon_{ij}(\lambda_g)}$$

- We add a new term that depends on the group g but not the product j and think about it as varying unobservably over individuals i just like  $\varepsilon_{ij}$ .
- Now  $\varepsilon_i \sim F(\varepsilon)$  where  $F(\varepsilon) = \exp[-\sum_{g=G}^G \left(\sum_{j\in J_g} \exp[-\varepsilon_{ij}/\lambda_g]\right)^{\lambda_g}$ . This is no longer Type I EV but a special kind of GEV.
- The key is the addition of the  $\lambda_g$  parameters which govern (roughly) the within group correlation.
- This distribution is a bit cooked up to get a closed form result, but for  $\lambda_g \in [0,1]$  for all g it is consistent with random utility maximization.

The nested logit choice probabilities are:

$$s_{ij} = rac{e^{V_{ij}/\lambda_g} \left(\sum_{k \in J_g} e^{V_{ik}/\lambda_g}
ight)^{\lambda_g-1}}{\sum_{h=1}^G \left(\sum_{k \in J_h} e^{V_{ik}/\lambda_h}
ight)^{\lambda_h}}$$

Within the same group g we have IIA and proportional substitution

$$rac{s_{ij}}{s_{ik}} = rac{e^{V_{ij}/\lambda_g}}{e^{V_{ik}/\lambda_g}}$$

But for different groups we do not:

$$\frac{s_{ij}}{s_{ik}} = \frac{e^{V_{ij}/\lambda_g} \left(\sum_{k \in J_g} e^{V_{ik}/\lambda_g}\right)^{\lambda_g - 1}}{e^{V_{ik}/\lambda_h} \left(\sum_{k \in J_h} e^{V_{ik}/\lambda_h}\right)^{\lambda_h - 1}}$$

We can take the probabilities and re-write them slightly with the substitution that  $\log\left(\sum_{k\in J_g}e^{V_{ik}/\lambda_g}\right)\equiv IV_{ig}=E_\varepsilon[\max_{j\in G}u_{ij}]$ :

$$s_{ij} = \frac{e^{V_{ij}/\lambda_g}}{\left(\sum_{k \in J_g} e^{V_{ik}/\lambda_g}\right)} \cdot \frac{\left(\sum_{k \in J_g} e^{V_{ik}/\lambda_g}\right)^{\lambda_g}}{\sum_{h=1}^{G} \left(\sum_{k \in J_h} e^{V_{ik}/\lambda_h}\right)^{\lambda_h}}$$

$$= \underbrace{\frac{e^{V_{ij}/\lambda_g}}{\left(\sum_{k \in J_g} e^{V_{ik}/\lambda_g}\right)}}_{S_{iil,g}} \cdot \underbrace{\frac{e^{\lambda_g I V_{ig}}}{\sum_{h=1}^{G} e^{\lambda_h I V_{ih}}}}_{S_{ig}}$$

This is the decomposition into two logits that leads to the "sequential logit" story.

## Nested Logit: Notes

- $ightharpoonup \lambda_g = 1$  is the simple logit case (IIA)
- $ightharpoonup \lambda_g 
  ightarrow 0$  implies that all consumers stay within the nest.
- $\lambda$  < 0 or  $\lambda$  > 1 can happen and usually means something is wrong. These models are not generally consistent with RUM. (If you report one in your paper I will reject it).
- $\triangleright$   $\lambda$  is often interpreted as a correlation parameter and this is almost true but not exactly!
- ▶ Because the nested logit can be written as the within group share  $s_{ij|g}$  and the share of the group  $s_{ig}$  we often explain this model as sequential choice. It could just be a block structure on  $\varepsilon_i$ .
- You need to assign products to categories before you estimate and you can't make mistakes!

### Parametric Identification

Look at derivatives:

$$egin{aligned} rac{\partial \, s_{ij|g}}{\partial X_j} &= eta_{\mathsf{x}} \cdot s_{ij|g} \cdot (1 - s_{ij|g}) \ rac{\partial \, s_{ig}}{\partial X} &= (1 - \lambda_g) \cdot eta_{\mathsf{x}} \cdot s_{ig} (1 - s_{ig}) \ rac{\partial \, s_{ig}}{\partial J} &= rac{1 - \lambda_g}{J} \cdot s_{ig} \cdot (1 - s_{ig}) \end{aligned}$$

- ▶ We get  $\beta$  by changing  $x_i$  within group
- $\blacktriangleright$  We get nesting parameter  $\lambda$  by varying X
- ▶ We don't have any parameters left to explain changing number of products J.
- Estimation happens via MLE. This can be tricky because the model is non-convex. It helps to substitute  $\tilde{\beta} = \beta/(1-\lambda_g)$

# A Confusing Gotcha

An alternative version of the nested logit is popular in IO (Cardell 1991)  $\sigma \approx 1 - \lambda$ :

$$egin{align*} s_{ij|g} &= rac{e^{V_{ij}/(1-\sigma)}}{D_{ig}} & D_{ig} &= \sum_{j \in \mathcal{G}} e^{V_{ij}/(1-\sigma)} \ & s_{ig} &= rac{D_{ig}^{(1-\sigma)}}{\sum_{g} D_{ig}^{(1-\sigma)}} & s_{ij} &= s_{ij|g} \cdot s_{ig} &= rac{\exp\left(rac{V_{ij}}{1-\sigma}
ight)}{D_g^{\sigma} \left[\sum_{g} D_g^{(1-\sigma)}
ight]} \end{aligned}$$

Derivatives for nested logit are complicated and worked out at http://www.nathanhmiller.org/nlnotes.pdf.

### Substitution Patterns

It is helpful to define:  $Z(\sigma, s_g) = [\sigma + (1 - \sigma)s_g] \in (0, 1]$  and note that  $Z(0, s_g) = s_g$  and  $Z(1, s_g) = 1$ . If two products are in the same nest or different nests respectively:

$$-rac{rac{\partial s_k}{\partial p_j}}{rac{\partial s_j}{\partial p_j}}$$
— same  $=rac{s_{k|g}}{Z^{-1}(\sigma,s_g)-s_{j|g}}\equiv D_{jk}^*$ 
 $-rac{rac{\partial s_k}{\partial p_j}}{rac{\partial s_j}{\partial p_j}}$ — different  $=rac{s_k(1-\sigma)}{1-s_{j|g}\cdot Z(\sigma,s_g(j))}\equiv D_{jk}^{**}$ 

These are related by:

$$D_{jk}^{**} = D_{jk}^* \cdot \frac{s_{g(k)} \cdot (1 - \sigma)}{Z(\sigma, s_{g(j)})}$$

#### **GEV Variants**

There are more potential generalizations though they are less frequently used:

- ➤ You can have multiple levels of nesting: first I select a size car (compact, mid-sized, full-sized) then I select a manufacturer, finally a car.
- ▶ You can have potentially overlapping nests: Yogurt brands are one nest, Yogurt flavors are a second nest. This way strawberry competes with strawberry and/or Dannon substitutes for Dannon.

# McFadden (1978) and GEV

In case you are wondering where these things come from...

$$s_{ij}(\mathcal{J}) = \frac{y_{ij} \cdot \frac{\partial G_i}{\partial y_j} (y_{i1}, \dots, y_{iJ})}{\mu \cdot G (y_{i1}, \dots, y_{iJ})}$$

With conditions on the generator function G:

- 1.  $G(\cdot)$  is homogenous of degree  $\mu > 0$  so that  $G(\alpha y) = \alpha^{\mu} G(y)$
- 2.  $\lim_{y_i \to +\infty} G(y_1, \dots, y_j, \dots, y_J) = +\infty$ , for each  $j \in \mathcal{J}$
- 3. the k th partial derivative with respect to k distinct  $y_j$  is non-negative if k is odd and non-positive if k is even that is, for any distinct indices  $i_1, \ldots, i_k \in \mathcal{J}$ , we have

$$(-1)^k \frac{\partial^k G}{\partial x_{i_1} \dots \partial x_{i_k}}(x) \leq 0, \forall x \in \mathbb{R}_+^J$$

The objects are more mathematical than economic...

# McFadden (1978) and GEV

This is much easier with an example:

$$s_{ij}(\mathcal{J}) = \frac{y_{ij} \cdot \frac{\partial G_i}{\partial y_j} (y_{i1}, \dots, y_{iJ})}{\mu \cdot G_i (y_{i1}, \dots, y_{iJ})}$$

- ▶ If  $y_j = e^{V_{ij}}$  and  $G_i = \log \sum_{i \in \mathcal{I}} y_{ij}$  we get the IIA logit.
- ▶ If  $y_j = e^{V_{ij}}$  and  $G_i = \sum_{h=1}^H \left(\sum_{j \in B_h} Y_{ij}^{1/\lambda_h}\right)^{\lambda_h}$  we get the nested logit.
- lacksquare ... if  $G_i = \sum_{h=1}^H \left( \sum_{j \in B_h} (\alpha_{jh} Y_{ij})^{1/\lambda_k} \right)^{\lambda_k}$  we get generalized nested logit (GNL).
- lacksquare ... if  $G = \sum_{k=1}^{J-1} \sum_{l=k+1}^J \left( y_{ik}^{1/\lambda_{kl}} + y_{il}^{1/\lambda_{kl}} \right)^{\lambda_{kl}}$  we get pairwise combinatorial logit (PCL).
- there are a number of other cross nested logit variants with slightly different setups (from each other).

#### **GEV** and Variants

#### What's next?

- Many of these GEV and variants are found in the engineering literature (particularly traffic problems, civil engineering, and industrial engineering).
- Economists tend to use either nested logit or mixed logit (next lecture).
- ▶ Part of the issue is that it is hard to understand the restrictions on the *G* function and the economic meaning of the patterns produced by some of these models.
- But they may be more parsimonious and easier to estimate than the alternatives.
