Grad IO

Mixed/ Random Coefficients Logit

An alternative is to allow for individuals to have random coefficients β_i:

$$U_{ij} = \beta_i x_j + \varepsilon_{ij}, \quad \beta_i \sim f(\beta_i | \theta), \quad \varepsilon_{ij} \sim \text{Type I EV}$$

As an alternative, we could have specified an error components structure on ε_i.

$$U_{ij} = \beta\, x_j\, y_i + \underbrace{x_j\, \nu_i + \varepsilon_{ij}}_{\tilde{\varepsilon}_{ij}}$$

▶ x_j are observed per usual, y_i are individual demographics/features, and ε_{ij} is IID Type I EV.

▶ The key is that ν_i is unobserved and mean zero (often normally distributed).

▶ This allows for a heteroskedastic structure on ε_i, but only one which we can project down onto the space of x.

Mixed Logit

We relax the IIA property by mixing over various logits:

$$\beta_i = \overline{\beta} + \Pi\,y_i + \Sigma\,\nu_i \qquad\qquad \mu_{ij} = x_j \cdot (\Pi\,y_i + \Sigma\,\nu_i)$$

$$u_{ijt} = x_j\beta_i + \varepsilon_{ij} \qquad\qquad\qquad = x_j\beta + \mu_{ij} + \varepsilon_{ij}$$

$$s_j(\theta) = \int \frac{\exp[x_j\beta_i]}{1 + \sum_k \exp[x_k\beta_i]} f(\beta_i|\theta) \qquad = \int \frac{\exp[x_j\beta + \mu_{ij}]}{1 + \sum_k \exp[x_k\beta + \mu_{ik}]} f(\boldsymbol{\mu_i}|\theta)$$

▶ Each individual draws a vector $\beta_i/\boldsymbol{\mu_i}$ (separately from $\boldsymbol{\varepsilon_i}$).

▶ Conditional on $\beta_i/\boldsymbol{\mu_i}$ each person follows an IIA logit model.

▶ However we integrate (or mix) over many such individuals giving us a mixed logit or heirarchical model (if you are a statistician)

▶ In practice these are not that different from linear random effects models you have learned about in econometrics.

▶ It helps to think about fixing $\beta_i/\boldsymbol{\mu_i}$ first and then integrating out over ε_i

$$s_{ij}(\theta) = \int \frac{\exp[x_j \beta_i]}{1 + \sum_k \exp[x_k \beta_i]} f(\boldsymbol{\beta_i}|\theta) \approx \sum_{s=1}^{S} w_i^s \frac{\exp[x_j \beta_i^s]}{1 + \sum_k \exp[x_k \beta_i^s]}$$

▶ We can only approximate the integral with weights w_i^s and nodes β_i^s
- We can allow for there to be two types of β_i in the population (high-type, low-type). latent class model.
- We can allow β_i to follow an independent normal distribution for each component of x_{ij} such as $\beta_i = \overline{\beta} + \nu_i \sigma$.
- We can allow for correlated normal draws $\beta_i \sim N(\mu_\beta, \Sigma_\beta)$.
- Can allow for non-normal distributions too (lognormal, exponential).
- Why is normal so easy?

▶ The structure is extremely flexible but at a cost.

▶ We generally must perform the integration numerically.

▶ High-dimensional numerical integration is difficult. In fact, integration in dimension 8 or higher makes me very nervous.

▶ We need to be parsimonious in how many variables have unobservable heterogeneity.

▶ Again observed heterogeneity does not make life difficult so the more of that the better!

  • If we see individual income, education, distance to hospital, etc. we can always interact that with observed characteristics without doing any additional integration.

Mixed Logit

How does it work?

▶ Well we are mixing over individuals who conditional on β_i or $\boldsymbol{\mu_i}$ follow logit substitution patterns, however they may differ wildly in their s_{ij} and hence their substitution patterns.

▶ For example if we are buying cameras: I may care a lot about price, you may care a lot about megapixels, and someone else may care mostly about zoom.

▶ The basic idea is that we need to explain the heteroskedasticity of $Cov(\boldsymbol{\varepsilon_i}, \boldsymbol{\varepsilon_\ell},)$ what random coefficients do is let us use a basis from our X's.

▶ If our X's are able to span the space effectively, then an RC logit model can approximate any arbitrary RUM (such as probit) (McFadden and Train 2002).

▶ Of course if you have 1000 products and two random coefficients, you are asking for a lot.

At the level of an individual substitution patterns follow a plain logit:

$$\epsilon_{s_j, p_j} = \frac{\partial s_j}{\partial p_j} \cdot \frac{p_j}{s_j} = \frac{p_j}{s_j} \cdot \int \frac{\partial s_{ij}}{\partial p_j} \, dF_i = \frac{p_j}{s_j} \int \beta_i \cdot s_{ij} \cdot (1 - s_{ij}) \, dF_i$$

$$\epsilon_{s_j, p_k} = \frac{\partial s_j}{\partial p_k} \cdot \frac{p_k}{s_j} = \frac{p_k}{s_j} \cdot \int \frac{\partial s_{ij}}{\partial p_k} \, dF_i = -\frac{p_k}{s_j} \int \beta_i \cdot s_{ij} \cdot s_{ik} \, dF_i$$

Notation: here $s_j \equiv s_j(x_i)$ denotes an individual choice probability (we re-use the i subscript) and $s_{ij}(\boldsymbol{\mu_i}) = s_{ij}$.

At the level of an individual substitution patterns follow a plain logit:

$$D_{jk,i}(x) = \frac{\frac{\partial s_{ik}}{\partial p_j}}{\left|\frac{\partial s_{ij}}{\partial p_j}\right|} = \frac{s_{ik}(x)}{1 - s_{ij}(x)}$$

But at the aggregate level, we mix over heterogeneous individuals:

$$D_{jk}(x) = \int D_{jk,i}(x) w_i(z_j, z_j', x) dF_i \quad \text{where} \quad w_i(z_j, z_j', x) = \frac{q_{ij}(z_j', x) - q_{ij}(z_j, x)}{q_j(z_j', x) - q_j(z_j, x)}$$

Different interventions (price changes, product removals, quality changes, etc.) give different weighting schemes.

How do we estimate these models? (Derived from multinomial log-likelihood):

$$\theta_{MLE} = \arg \min_{\theta} - \sum_{i=1}^{N} \sum_{j=1}^{J} y_{ij} \ln \hat{s}_{ij}(\theta)$$

▶ We need to perform numerical integration to get $\hat{s}_{ij}(\theta)$ and its derivative: $\widehat{\frac{\partial s_{ij}}{\partial \theta}}$.

▶ Consistency
  • Technically for fixed number of MC draws the MSLE estimator is inconsistent. Why?
  • Very accurate integration is even more important!

Can also do a simulated GMM estimator with moment conditions:

$$\mathbb{E}\left[\left(y_{ij} - \hat{s}_{ij}(\theta)\right)|z_{ij}\right] = 0$$

▶ We need to perform numerical integration to get $\hat{s}_{ij}(\theta)$ and its derivative: $\widehat{\frac{\partial s_{ij}}{\partial \theta}}$.

▶ The optimal instruments in the sense of Chamberlain (1987) or Amemiya (1977) are the derivative of moments with respect to parameters (scores): $z_{ij} = \frac{\partial \log s_{ij}}{\partial \theta}(\theta)$.

▶ The true scores are infeasible (they depend on θ_0).

   • At true scores: same FOC as MLE.
   • Simulated scores have same consistency issue as MSLE.

As an alternative we could work with the score function directly:

$$\sum_{i=1}^{n} \frac{\widehat{\partial \log s_{ij}}}{\partial \theta}(\theta) = \sum_{i=1}^{N} \frac{1}{\widehat{s_{ij}}(\theta)} \cdot \frac{\widehat{\partial s_{ij}}}{\partial \theta}(\theta) = 0$$

▶ We can get unbiased estimated of derivative (linearity)
▶ We can't get unbiased estimate of $\frac{1}{\widehat{s_{ij}}(\theta)}$
  • Train's book suggests Accept-Reject
  • Maybe importance sampling would work?

How bad is the simulation error?

▶ Depends how small your shares are.

▶ Since you care about $\log s_{jt}$ when shares are small, tiny errors can be enormous.

▶ Often it is pretty bad.

Estimation Details: Recommendations

You should read these separate notes, but my recommendations are:

1. Numerical integration:
   - Use Gauss-Hermite quadrature rules to integrate over normal densities.
   - Follow Heiss and Winschel (JoE) and do sparse grids in medium dimensions
   - Try http://sparse-grids.de.

2. Nonlinear optimization: with mixtures the problem is non-convex (ie: very hard)
   - You must provide analytic gradients.
   - You should use a quasi-Newton solver and may need to try several.
   - Try multiple starting values.

3. Generalized Method of Moments
   - You can read more about optimal IV in these settings.
